COMPLAINT COMPASS · SCALABILITY IN ONE MINUTE

Say this, then stop

> “Our pipeline has two steps. **Classifying** a complaint is the slow part, and it doesn’t touch shared data, so we scale it horizontally: run as many workers as the queue needs. **Filing** changes the issue list, so each business area gets exactly one writer, and all areas run in parallel. It’s the standard single-writer-per-partition pattern. Only about 4% of complaints reach the LLM, so cost grows linearly: about $433 a month at 10 million complaints.”

The three points behind it

1. **Classify = scale out.** It’s 0.53 s of the 0.55 s per complaint, all waiting on Jev, and it needs no shared data. More workers, more throughput.
2. **File = one writer per area.** Two writers on the same issue list could create the same new issue twice. One writer per area (payments, delivery…) prevents that, and areas don’t wait for each other.
3. **Grow by adding, not redesigning.** More traffic: more classifier workers. A busy area: split it (e.g. by region). A new company: its own areas.

Three numbers

96.1%
of complaints never reach an LLM (measured)

$4.33
model cost per 100,000 complaints (measured)

~2 / sec
all Indian quick commerce on average; one classifier worker handles ~15 (projected)

If they ask one more thing

“What if the writer dies?”	“Another worker takes over that area and rebuilds its issue list from the database.”
“Is $4.33 your price?”	“No, it’s our model cost. We price per complaint processed.”
“Is it built and tested?”	“Designed, not built. Numbers come from measured timings; a load test is our first proof point.”

Measured on the live run of 1,500 complaints (Jev 1.14 and Claude Haiku 5.5). Projections assume 2% of 7.8M daily orders lead to a complaint. Full detail: Scalability_Answer_Guide.pdf.
